**Abstract**— The vehicles are equipped with electronic control units that control their functions. These units communicate with each other via in-vehicle communication protocols like CAN bus. Although CAN is the most common in-vehicle communication protocol, its lack of encryption and authentication can cause serious security shortcomings. In the literature, many attacks are reported related to CAN bus and the number increases with rising connectivity in the cars. In this paper, we present CAN protocol and analyze its security vulnerabilities. Then we survey the implemented attacks and proposed solutions in the literature.

**Keywords**—CAN bus, in-vehicle communication, CAN bus security, electronic control unit

## I. INTRODUCTION

The modern vehicles are equipped with around 100 Electronic Control Units (ECUs) to control the electrical systems to improve driving comfort and safety[1][2]. ECUs control most of the car's functions including safety-critical functions like engine control, airbag deployment, and anti-lock braking system. To have a safe driving, ECUs should have a reliable communication network. One of the main in-vehicle communication protocols is Controller Area Network (CAN). Its well-recognized advantages, such as high immunity to electrical interference, easy wiring, ability to self-diagnose, and repairing errors, make CAN bus suitable for the automobile industry. Although CAN is resilient to electrical noise and has security features, it is still vulnerable to attacks. As security of systems is becoming a significant concern, extensive research on vulnerabilities of CAN carried out to find possible solutions. Some of these studies performed successful experimental attacks on commercial cars. While most attacks are implemented via physical access to the bus, wireless attacks are increasing. With the new wireless interfaces like vehicle-to-vehicle and vehicle-to-infrastructure, wireless attack surface will increase. We believe that wireless attacks will become the main attack surface for the future attacks.

This paper aims to i) analyze the security of CAN protocol ii) show the vulnerabilities of modern cars, and iii) present the solutions from the literature after identifying the attacks. The rest of the paper is structured as follows: In Section II the general overview of CAN protocol with security shortcomings are given. In Section III implemented attacks and proposed solutions in the literature are surveyed. In Section IV the work is summarised and the paper is concluded.

## II. BACKGROUND

### A. Controller Area Network

CAN protocol, developed by Robert Bosch GmbH in the early 1980s, is a multi-master communication interface designed for the in-vehicle communication. It is a broadcast

network and can provide up to one megabit per second (bps). CAN bus has high immunity to electrical interference, is easy to wire, and has ability to self-diagnose and repairing errors. The distributed architecture of the network makes maintenance easier and decreases the overall system cost.

The robustness of CAN comes from the built-in security features. CAN protocol uses differential wiring to eliminate the noise and has two voltage levels: dominant logic '0' and recessive logic '1'. Hence there is no dedicated clock line, synchronization is provided via signal edges and bit-stuffing. Bit-stuffing rule limits the number of repeated bits. After five consecutive bits of the same logic level, the next bit must be the complement of the previous logic level. If the data has more than five successive corresponding bits, a complement bit is inserted by transmitter CAN controller and it is ignored by the receiver CAN controller.

Collision Detection and Arbitration on Message Priority (CD+AMP) resolves the collisions with the help of message identifier bits. When two nodes start transmitting at the same time, a higher priority node continues to transmit and other node/s will stop transmitting. Another collision prevention mechanism is Carrier Sense, Multiple Access with Collision Avoidance (CSMA/CA) which rules the nodes to wait for a certain amount of inactivity before transmitting the data to sense the node is idle and collision will not occur.

Fig. 1. The bits of standard CAN bus frame

There are also five error checking methods, which are Start of Frame (SOF) single dominant bit for synchronization, Cylindrical Redundancy Check (CRC) checksum of the data for data integrity, Acknowledgement (ACK) bits for successful data transmission, and End of Frame (EOF) bit for stuffing error and frame finalization.

CAN protocol is also resilient to physical errors. It can eliminate the faulty nodes from the bus traffic with Error Confinement Mechanism (ECM). ECM utilizes two error counters in each node; Received and Transmitted Error Counters. The value of counter increases by eight at the occurrence of an error during the transmission and by one at the occurrence of an error during the receiving. Then node will enter the Error Passive state if the counter's value exceeds 127; however, its error frames will not affect the bus traffic. If the counter value exceeds 255, the node will be in the Buss-Off state and will no longer take part in the bus traffic.

### B. Security Shortcomings of CAN Protocol

When CAN bus was initially designed in the early 1980s, security was not the main consideration. It was used to connect a few ECUs and was not accessible to the end user. However, the automobile industry has changed drastically and now there are dozens of ECUs connected and it is required by law that bus should be accessible for the diagnostic purpose[3].

Although CAN has many security features, it can be still attacked. The main problem with CAN protocol is lack of encryption and authentication. The lack of authentication allows any unauthorized nodes to join the network and take part in the communication. CAN is a broadcast network, so there is no source and destination addresses and every node can listen to any messages. As the data is not encrypted, an adversary can listen and understand the data. This may cause privacy problems because modern cars also collect data related to drivers like location and address book. It also allows an adversary to inject faulty data on the system.

CAN protocol is also vulnerable to Denial of Service (DoS) attacks. Arbitration mechanism of CAN allows higher priority nodes to speak first. If a malicious node with the highest priority is active all the time, the other nodes cannot communicate because of the prioritization in CAN bus. Another example of DoS attack implementation is a misuse of ECM. If an attacker generates an error during the communication, this will increase the error counters and eventually cause the elimination of the node.

## III. RELATED WORK

In this section CAN bus is analyzed and the attacks with the proposed solutions from the literature are presented.

### A. Security Analysis of CAN Network

In this chapter, CAN protocol is analyzed based on CIA (Confidentiality, Integrity, and Availability) triad. CIA triad is a simple security model to assess the system vulnerability. The CIA triad analyses three essential principles, which any secure system should have.

Confidentiality means providing the data to only authorized people. Cryptographic and encryption methods are used to provide confidentiality. Although CAN protocol does not have inherent security measures for confidentiality, some car manufacturers use cryptographic methods for local functionalities like keyless entry[4].

Integrity is defined as the accuracy and validity of the data. The data must not be changed during the transmission. CAN has Cylindrical Redundancy Check (CRC) checksum for verification of integrity, so if any bit is corrupted during the transmission, it can be detected by the receiver. But the CRC cannot detect the altered data from the malicious node because there is no authentication provided by CAN protocol. Therefore CAN protocol fails to sustain the integrity of the data.

Availability means the data or the network can be accessed by the authorized user at all times. This is not possible by the nature of CAN protocol because of the arbitration rule and physical implementation of the protocol. The arbitration rule allows the higher priority node to access the network. If a node with the highest priority transmits the data all the time, the bus is not accessible to the other nodes.

### B. Existent Attacks

In this chapter, the attacks that have been implemented in the literature are presented. The first known attack on CAN bus is implemented on the electric window lift on the simulation environment by Hoppe and Dittman in 2007[5]. Since then, different attack scenarios have been implemented. The attacks can be categorized into three main categories: eavesdropping, data insertion, and denial of service (DoS).

Eavesdropping is the starting point of many attacks. Lack of encryption allows any node to understand the bus traffic, so an adversary can sniff CAN frames and gather the information. This may cause an invasion of privacy. The modern car collects information about the driver and has the capability to connect to the driver's mobile phone. The adversary can steal this personal information by only passively listening to the bus. Enev et al. [6] show that it is possible to identify the driver based on the sensory data travel through the CAN bus. They were able to identify 15 drivers with 100% accuracy. The research says that it is also possible to identify the driver with even one sensory data (e.g. brake pedal). They successfully show that monitoring in-vehicle network can invade personal privacy. Eavesdropping can be classified as passive attack hence it is not disturbing the communication. However, it can lead to active attacks. For instance, Palanca et al. [7] captured CAN frames and identify the ID of the node they planned to attack. When they gathered the ID and data of the parking sensor, they implemented a DoS attack.

Data insertion can be defined as the insertion of the unauthorized CAN frame to the network. As CAN protocol does not have an authentication mechanism a malicious node can attach to the network and insert data. Frame falsifying, frame injection, and replay attacks are examples of the data manipulation. Koscher et al. [8] were able to hack the instrument cluster, body control module, brake control module, and engine control module. They connected a laptop to On-Board Diagnostics II (OBD-II) port and implemented their attacks on a real car. They manipulated the fuel level and speedometer readings and showed false data on the instrument cluster. This research was able to disable the engine and change the engine parameters like timing and RPM. They released the brakes and prevented their activation with continuous fuzzing method, while the car was running 40MPH. Hoppe et al. [4] implemented four different attack plots and analyzed their effects based on comfort, security, and safety. One of the attacks was removing the airbag warning. The attack can hide the theft event while endangering the passengers' lives. This research shows that the driver cannot rely on the system's security checks although manual checking is infeasible.

Denial of Service (DoS) is preventing any particular node/s or the whole network to provide service. There are different types of the DoS attacks implemented on CAN network. Mukherjee et al. [9] implemented DoS attacks on SAE J1939. SAE J1939 standard is used in commercial vehicles and it is implemented on top of the CAN physical layer. They implemented three separate DoS attack. The attacks were i) sending too many request messages for a supported Parameter Group Number (PGN) to overload recipient ECU, ii) sending manipulated False Request to Send (RTS) and causing overflow at the recipient buffer, and iii) keeping the connections open via Clear to Send (CTS) messages and occupy the whole network. This work shows

that the protocols implemented on top of CAN's physical layer is also vulnerable to attacks. Palanca et al. [10] implemented selective DoS attack by attaching a stealthy node to the network. They have implemented the attack based on CAN protocol's weakness, therefore, any car with CAN bus is vulnerable. The malicious node overwrites the bits and generates error frame. Because of CAN's error confinement, after a certain number of error occurrence, the transmitter node will go to the bus-off state and will no longer be available. The attack is implemented on 2012 Alfa Romeo Giulietta. The attack method can disable any node connected to the bus. However, they disabled the parking sensor for the ethical reasons. This attack is different from other DoS attacks because it does not transmit a whole CAN frame to the network.

Some critics say that the physical access requirement of CAN attacks make them infeasible[11]. Although the attacks mentioned above require the physical access to the CAN network, there is an increase in the number of remote attacks. The modern cars are equipped with different types of wireless interfaces: passive anti-theft system, tire pressure monitoring system (TPMS), remote keyless entry, Bluetooth, radio data system, and telematics. These wireless interfaces may have communication with CAN network via a gateway ECU which has a firewall. Some researchers pass over the firewalls and gain access to the CAN network. Checkowat et al. [12] compromised TPMS, Bluetooth, FM channel, and cellular network of a car and modified the ECU. With this method, they claim that a thief can steal a car as the car doors can be unlocked via the CAN network. Woo et al. [13] implemented a remote attack via malicious self-diagnostic smartphone app. If a driver downloads a malicious app to monitor/diagnose the car, he/she allows the adversary to take control of the car without attaching any device physically. Then, the attackers can implement their attack from long distance via using the phone's internet. Valasek and Miller [14] carried out remote attack survey on 12 car brands and 21 commercial cars. They have identified the remote attack surfaces and their difficulties to compromise each car. The attack was three staged. The first stage was compromising the ECU responsible from wireless interface. The second stage was injecting messages to communicate with the safety-critical ECU. The last stage was modifying the ECU to behave maliciously. The researchers believe that the increasing number of cyber-physical systems in the cars will increase their vulnerabilities, but they cannot practically verify this, because of the high number of different applications in the cars.

Another wireless attack method is over-the-air (OTA) software update. OTA provides the manufacturers to reprogram the ECU to patch software bugs or add new features. It provides flexibility and saves money. But it is another attack surface that hackers can dive into the car's communication network. There is no reported attack related to OTA updates yet but it should be considered as a critical threat.

### C. Proposed Solutions

The attacks on CAN bus are analyzed and some solutions are put forward in this section. The solutions can be categorized as network segmentation, encryption methods, authentication methods, and intrusion detection systems.

The simplest way to provide security is changing the network topology. Critical ECUs and non-critical ECUs are

separated and the end user cannot access the critical ECU network easily. The connection between networks is provided via a gateway ECU. This security measure is already implemented on commercial cars. However, the gateway ECU can be manipulated and the critical network can be accessed. If the gateway ECU is programmed to pass relevant IDs to the subnetwork, it can be fooled by sending malicious CAN frame with an ID of a node which belongs to the subnetwork[4]. Kammerer et al. [15] implemented star coupling router topology. The router not only separates the single-bus based CAN system to the multiple CAN segments, but also brings new security features like unidirectional channels, traffic shaping, traffic partitioning, message integrity, and intrusion detection. In the paper, CAN segment security was taken out of the scope. However, it is possible for the replay or masquerade attacks in a CAN segment to pass the router's security checks and attack the other CAN segments. The safest solution will be a node in a segment but it is not feasible in the perspective of cost and time. Also, the network segmentation might increase the maintenance difficulty as compared to the traditional CAN network.

Due to the broadcast nature of the CAN protocol, any node can listen to the bus traffic. As CAN system does not have an encryption mechanism, an adversary can listen to CAN traffic easily and understand the communication. To prevent attacks and provide confidentiality, different encryption mechanisms are proposed in software and hardware levels. Some Software-based encryption methods are commercially available (e.g. TRILLIUM [16]) and some manufacturers implement propriety encryption techniques on their commercial cars. However, software-based encryption methods are not strong enough because of the low computational power which results in a weak encryption mechanism. There are also reports that claim some of the encryption mechanisms on commercial cars are broken[17]. ECUs do not have much computational power, therefore, software-based encryption can cause latency which is not acceptable for the safety-critical automotive industry. The limited bandwidth is also another restriction. Software-based encryption may work with a limited traffic, but it is not promising for the currently increasing CAN traffic. Shreejith and Fahmy [18] proposed FPGA based zero latency encryption. They enhanced the network protocol layer. The encryption and decryption processes are done while the data is buffered at the network layer. This will prevent any additional latency. However, if we consider the automotive industry and cost of ECU, FPGA based solutions are luxury. Any change in protocol layer will also require custom-made CAN controllers which is not feasible to change.

In the current CAN protocol, it is not possible to trace a CAN frame and find its source. There is also no authentication which means that any node can attach to the network and send messages. If a malicious node injects a CAN frame, other nodes will accept it and process. To prevent data injection to CAN network, some authentication methods are proposed. Wang and Sawhney [19] proposed VeCure authentication method with only 50us processing delay. The authentication mechanism works based on trust groups where high-trust group/s share a symmetric secret key. The authentication is achieved by sending data message followed by an authentication message. The latency of the proposed method can be ignored but the bus traffic is doubled in the high-trust group which is not acceptable if we consider the limited bandwidth in CAN protocol. Although this method decreases the number of keys and the key number is independent of the

ECU number, it will fail to protect the system if there is a compromised node from the trust group. Woe et al. [13] proposed an encryption and authentication method using AES-128 and a 32-bit truncated message authentication code (MAC). The proposed method latency is about 378us at 60MHz. They claim that latency will decrease if the proposed protocol implemented on Application Specific Integrated Circuits (ASICs). Although this method looks promising, it is not compatible with the standard CAN protocol. Another drawback of this method is using the symmetric key at the initial stage of the communication. If we consider a car's average life 20 years, brute force attack can be implemented to compromise the method. Nowdehi et al. [20] identified five criteria for authentication systems to be implemented in commercial cars. These criteria are cost-effectiveness, backward compatibility, support for vehicle repair and maintenance, sufficient implementation details, and acceptable overhead. They have tested 10 methods they have found in the literature including the methods mentioned above. Not surprisingly, none of the methods can pass all the five criteria. The CAN protocol was not designed with security in mind, therefore, it is hard to find a feasible security solution.

Siddiqui et al. [21] proposed a Physical Unclonable Function (PUF) based encryption and authentication and provide secure communication over CAN bus. They used elliptic curve Diffie-Hellman based asymmetric encryption method also called as public-private key cryptography. Asymmetric key encryption is safer than symmetric key encryption, but it requires high computational power for current ECU controllers. According to their data, AES-128 encryption generates 366.66ns and 110ns latency at 60MHz and 200MHz clock frequency respectively. However, most of the ECUs have limited computational power like clock speed of tens of MHz[19]. In reality, latency will increase significantly. The other negative side of this proposal is that it requires hardware change in the CAN controller and a server to authenticate the nodes. This will increase the system cost and having a server can create other potential attacks. Murvay and Groza [22] proposed to analyze signal pattern to gather footprints of the transceivers to authenticate the node. The proposed method does not increase the traffic or change the CAN controller but it requires intensive signal processing. If the network is compromised by a software attack, the method will fail.

CAN protocol has obvious security vulnerabilities. Implementing security features to CAN bus is a challenging job due to limited resources (bandwidth, memory, and computational power) and time constraint. This lead to extensive research on intrusion detection/prevention system (IDS/IPS). The main advantages of IDS/IPS is it does not modify the current CAN system and the bus traffic will not increase. IDS analyses the CAN traffic and detect the abnormalities. If any abnormality is detected, they warn the driver. The difference of the IPS from IDS is that they can take an active role and prevent the attack. Basic IDS is based on the frequency analysis of the CAN frames like the one in [23]. Most of the CAN nodes transmits periodic messages and change in the frequency can be interpreted as an intrusion. However, there are some attacks which do not change the message frequency like a masquerade attack proposed in [24]. Therefore more complex algorithms are required like behavioral analysis of the network traffic. Fang et al. [25] implemented an adaptive-network-based fuzzy inference

system. They use information like busload, change in message number in a certain period, and a number of dropped messages and messages with illegal ID. They implemented the five-level Sugeno algorithm and trained the network. They tested their method on a commercial electrical car. The proposed method detected the attacks implemented by the researchers but it is questionable that it will prevent complex attacks. Another IDS methodology is analyzing the electrical characteristics of the signal[26][22]. The idea behind this method is each transceiver has a different signal shape even while transmitting the same data. This can be caused by variations in CAN physical layer implementation by different manufacturers, cabling, and manufacturing process variations. The authentication method proposed by Murvay and Groza [22] can be also considered as IDS because it has the ability to detect malicious nodes.

We believe that the best IDS solution can be a combination of the signal characteristics and network data analysis. Signal characteristic will detect the malicious node added to the CAN network by an adversary. However, if an attack from software level is implemented, the signal characterization cannot detect the intrusion. Therefore, the traffic data should be analyzed and combined with the signal characteristic. There are also some commercial intrusion detection systems [27][28] but their algorithms are not shared with the public.

#### IV. CONCLUSION

In this paper, we explained the CAN protocol and its vulnerabilities. We analyzed the security of the protocol using CIA triad. Although CAN is the most widely used in-vehicle communication protocol, it fails all three benchmarks of CIA triad. The lack of encryption and authentication mechanism causes multiple attacks. We summarised the implemented attacks from the literature. Although most of the attacks implemented require the physical access to the CAN network, wireless attacks are increasing. We estimate that wireless attacks will increase and surpass the physical access attacks. The reason behind this idea is cars are getting more connected and this will increase the attack surface.

Extensive research carried out to find a solution to CAN security vulnerabilities. We categorized the proposed solutions. Some solutions provide large overhead to the limited bandwidth and some change the standard CAN controller. There is no optimal solution as CAN system was not designed with the security in mind. As a result, there is no approved solution by the industry or the academia. The problem is mitigated with network segmentation and IDS. Although IDS does not provide complete solutions, some commercially available methods do deal with the CAN vulnerabilities.

CAN protocol does not provide a secure communication intrinsically. Implementing a strong encryption and authentication system is impractical because of the bandwidth and time-constraints. Therefore, the most secure solution can be obtained by a hybrid system which consists of encryption, authentication, and IDS. The future researches should focus on hybrid systems. It is also important to limit the wireless interfaces hence they can create new attack surfaces. If it is essential to implement a wireless interface, it should be isolated as much as possible and strong gateway ECU must be placed. These can be short-term solutions. In the long-term, CAN protocol should be placed with a new protocol which has intrinsic security.

## ACKNOWLEDGMENT

The authors would like to thank Cordelia Mattuvarkuzhali Ezhilarasu for her valuable comments and suggestions to improve the quality of the paper.
